PREFACE

Program COYIELD presented here is available to interested users in either a FORTRAN batch version for mainframe computers or in IBM BASIC for the Personal Computer. A punched card deck of the FORTRAN version or a diskette of the BASIC version can be obtained by writing the Biometrics Section, School of Forestry and Wildlife Resources, Virginia Tech, Blacksburg, VA, 24061.

A charge of \$20.00 applies to either version to cover the cost of copying and mailing. Checks should be made out to the Department of Forestry, VPI & SU.

Although the software, to the best of our knowledge, contains no errors, neither Virginia Polytechnic Institute and State University, the School of Forestry and Wildlife Resources nor the authors claim any responsibility for its accuracy.

ACKNOWLEDGEMENTS

The work reported here was sponsored by the Loblolly Pine Growth and Yield Research Cooperative at VPI and SU. Support from Bowater Incorporated, Champion International Corporation, Chesapeake Corporation, Continental Forest Industries, Crown Zellerbach Corporation, Federal Paper Board Company, International Paper Company, Potlatch Corporation, Union Camp Corporation, Westvaco Corporation, Weyerhaeuser Company, North Carolina Division of Forestry, Virginia Division of Forestry and the U.S. Forest Service (by Cooperative Agreement) is gratefully acknowledged.

The input and output subroutines for program COYIELD were based on similar routines developed by Quang V. Cao (Cao *et al.* 1982) for program WTHIN. His contribution is appreciated.

AUTHORS

The authors are Research Associate, Thomas M. Brooks Professor and Graduate Research Assistants, respectively, in the Department of Forestry, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061.

ABSTRACT

Data from plots established in unthinned loblolly pine plantations on cutover site-prepared lands were used to develop size class distribution and yield predictions. The data come from plantations of loblolly pine established over much of its natural range and represent a wide variety of stand conditions and site-preparation treatments. A three parameter Weibull density function was used to model diameter distributions, and a computer program, COYIELD, was developed to predict yields from stand attributes. The predicted yields should satisfactorily represent many sites in the Piedmont and Coastal Plain regions of the Southern United States.

INTRODUCTION

During the 1950's and early 1960's, most of the loblolly pine plantations in the South were established on abandoned agricultural lands. Growth and yield relationships for these sites have been thoroughly researched and a number of yield prediction systems for them exist (Burkhart *et al.* 1981). Since then, the majority of plantations have been established on cutover sites receiving some type of site preparation treatment prior to planting. In order to effectively manage these lands, estimates of yields for various product objectives are needed.

The purpose of this study was to develop a size-class distribution model to predict yields of unthinned loblolly pine plantations on cutover site-prepared lands. The model presented here, program COYIELD, should provide satisfactory yield estimates for many different stand conditions over much of the natural range of loblolly pine. Versions of COYIELD were developed in FORTRAN for mainframe computers and in BASIC for the IBM Personal Computer.

BACKGROUND

Yield models developed for cutover, site-prepared lands have been few due primarily to a scarcity of data. Feduccia *et al.* (1979) published a diameter distribution model for predicting yields in unthinned loblolly pine plantations on cutover sites in the West Gulf Coastal Plain. Clutter *et al.* (1984) developed a similar model based on data from the lower Coastal Plain areas of North Carolina, South Carolina and Georgia. These studies included data from a rather limited portion of the natural loblolly range.

Using the region-wide data discussed here, Burkhart *et al.* (1984) applied multiple regression techniques to predict total yield of the planted pine from stand variables such as age, average height of the dominant and codominant trees and surviving number of loblolly pine per acre. In their analysis, they found that variables describing the planted pine component of a stand were sufficient for predicting the yield of the planted pine, except at relatively high levels of hardwood competition. For these data, inclusion of variables describing the hardwood overstory and/or understory did not significantly improve prediction. In addition, a single yield equation and survival

equation were found to be adequate for all site preparation methods and physiographic regions. Further, the height of dominants and codominants versus age relationship was found to be similar for different site preparation treatments within the Coastal Plain and Piedmont regions but was significantly different between them. Clutter *et al.* (1976) found similar results in their analysis of relationships in slash pine plantations on site-prepared areas.

These findings suggest that stand age, average height of dominant and codominant trees and the number of planted pine surviving are adequate for predicting yields of the planted pine. (In the data used to develop program COYIELD, the percent of total basal area in the main canopy in hardwoods ranged from 0 to 27.8 and averaged 4.8.) They also imply separate coefficients for different site preparation treatments and geographic locations are not necessary. Program COYIELD was developed in light of these findings and produces yield estimates which represent a broad range of stand conditions and geographic localities.

DATA

Data for this study came from 186 plantations in which plots were established during the 1980-1981 and 1981-1982 dormant seasons. Initial measurement data from these plots were used for this study. Figure 1 and Tables 1 and 2 summarize the location and type of site preparation treatment information for these stands.

To be included in the sample, the plantations had to be at least eight years in age (defined as years since planting), unthinned, free of evidence of heavy disease or insect attack, not heavily damaged by ice or wind storms, free of interplanting, unpruned, not fertilized within the last four years, not planted with genetically improved stock, contain a minimum of 200-300 planted pine stems per acre that appear "free to grow", not more than 25 percent of the main canopy composed of volunteer pines, and established on a cutover area that received "typical" site preparation treatment for the site conditions and time at which the plantation was established.

In each stand, a set of three comparable, but not necessarily contiguous, plots was established. To be judged "comparable" the maximum spread in site index could not exceed

five feet (25-year base). Initial stocking was considered comparable if the maximum spread in trees per acre did not exceed 100 and the range in basal area did not exceed 20 square feet per acre for the three plots. The three plots were combined to form one analysis plot approximately 0.5 acres in size. Tables 3 and 4 provide a summary of the range of stand attributes in the data for these analysis plots.

General information collected for each plot included the type of site preparation, whether or not fertilized or released, age since planting and, in some cases, the number of trees planted.

The data recorded from all planted pine included dbh to the nearest 0.1 inch, total height to the nearest foot, height to the base of the live crown, crown class and stem quality assessment. A total of 56,989 planted pine was available for analysis.

The model presented here was developed using the initial measurements from a large, region-wide data set. Some components of the model come from the literature. Once remeasurement data become available, the model will be validated and, if necessary, modified and refined.

The next section of this report is a technical discussion of each component of COYIELD and may be skipped by those interested only in using the model.

a/ Computed using equation from Amateis and Burkhart (1984) with coefficients from combined Coastal Plain and Piedmont data.

DEVELOPING THE MODEL

Six components were integrated into a computer program called COYIELD, which was written in standard FORTRAN and IBM BASIC for predicting yields of unthinned loblolly pine plantations. The six components include input, site index, mortality, diameter distribution, height-diameter curve and output. COYIELD will project a stand through time from any point in the rotation. The FORTRAN version will also produce stand and stock tables for various combinations of age, site index and number of trees planted per acre. Following is a discussion of each component in the model.

Input

Input to the FORTRAN version of program COYIELD comes through one of two subroutines (Appendix 1a). Subroutine INPUT1 reads the necessary information for projecting a stand. Projection can be made starting at age 0 or at any point in the rotation using either number of pines planted or number surviving. Appendices 1b and 1c list the variables and associated formats for INPUT1. The BASIC version is interactive and prompts the user for the appropriate inputs.

Subroutine INPUT2 (FORTRAN version only) reads information for producing stand and stock tables for various combinations of age, site index and number of trees. Appendix 1d lists the variables and associated formats for INPUT2.

The user also has the option to specify a merchantability limit based on top diameter outside bark and diameter class limit, to print a title with the output, and to select between Coastal Plain, Piedmont or combined site index equation coefficients.

Site Index

The site index equation used in COYIELD is based on stem analysis data of dominant and codominant trees from the 186 plots used in this study (Amateis and Burkhart, 1984). In COYIELD, average height of dominant and codominant trees is predicted from equation (1) in subroutine HEIGHT

$$\ln(H_d) = \ln(S)((1/A)/(1/25))^{b_1 e^{b_2(1/A-1/25)}} \quad (1)$$

where H_d = average height of dominant and codominant trees (feet)
 S = site index in feet (25-year base)

A = plantation age in years
 \ln = natural logarithm
 e = base of the natural logarithm
 b_1, b_2 = coefficients corresponding to Coastal Plain,
 Piedmont or combined data for equation (1);
 values of which are shown below.

	b_1	b_2
Combined Coastal Plain and Piedmont	-0.10283	-2.1676
Coastal Plain	-0.11092	-1.9036
Piedmont	-0.08596	-2.6055

Selection of the value for variable ISITE (Appendix 1b) in the input determines which set of coefficients, b_1, b_2 is used in the model

```

ISITE = 1 - Combined Coastal Plain and Piedmont
coefficients
= 2 - Coastal Plain coefficients
= 3 - Piedmont coefficients
  
```

Evaluation of the three sets of coefficients suggests there is often little practical difference between them above age 15. Thus, for many purposes, it may be satisfactory to use the combined Coastal Plain and Piedmont coefficients. Figure 2 shows the relationship between curves for the Coastal Plain and the Piedmont for site index values of 50, 60, and 70.

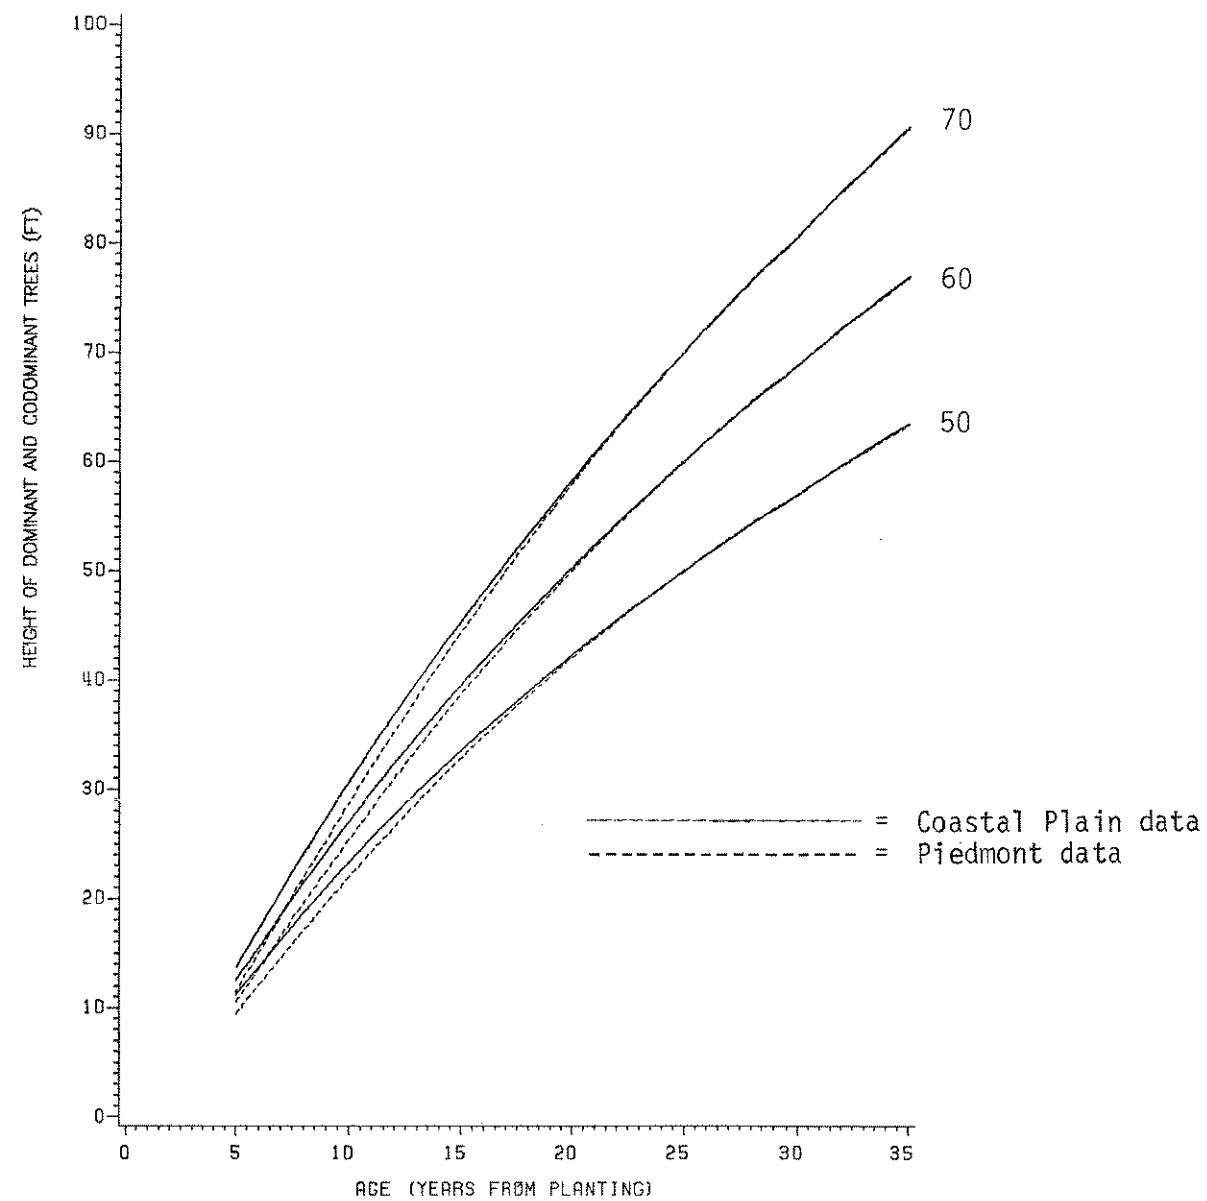

Figure 2. Site index curves developed using data from Coastal Plain and Piedmont sites for cutover, site prepared loblolly pine plantations.

Mortality

Since remeasurement data were not available to develop a survival equation for these stands, a number of published equations were evaluated using the 75 plots which had an estimate of the number of trees planted at stand establishment. The equations considered were Coile and Schumacher (1964), Feduccia et al. (1979), Lenhart (1972), Lenhart and Clutter (1971), Smalley and Bailey (1974) and Clutter et al. (1984). From the number of trees planted, a predicted number of trees surviving at the time of plot establishment was obtained from each equation. Predicted and observed surviving number of trees were compared. Of the equations tested, the Feduccia et al. (1979) equation

$$\log(Np/Ns) = A(0.01348 \log(Np) + 0.0006078 Hd - 0.008412 \sqrt{Hd})$$

where

Np = number of pines planted (trees/ac)

Ns = number of pine surviving (trees/ac)

A = age (years from planting)

Hd = average height of dominant and codominant pine (ft)

log = logarithm base 10

produced the smallest mean and mean absolute residuals. Examination of residual plots suggests that this equation performs satisfactorily for most combinations of A, Np, and Hd. Also, trends in the residuals were not evident across site preparation treatment and geographic or physiographic locality.

Diameter Distribution

The three-parameter Weibull probability density function given below was used to approximate the diameter distribution.

$$f(x) = (c/b) [(x-a)/b]^{c-1} e^{-[(x-a)/b]^c}$$

where

a = location parameter

b = scale parameter

c = shape parameter

x = diameter random variable.

a, b, c > 0

x > a

The location parameter, a was obtained by determining the maximum likelihood estimate for a for each plot. These estimates were then regressed on stand characteristics to develop a suitable prediction equation. The scale and shape parameters, b and c were predicted according to procedures discussed by Bailey et al. (1982) for site-prepared slash pine plantations.

Given the Weibull cumulative distribution function,

$$F(x) = 1 - e^{-[(x-a)/b]^c} \quad (2)$$

where $F(x)$ = the proportion of trees per acre having diameters less than or equal to x , and a, b, c are as defined previously,

an equation for the p th percentile, X_p , in terms of p , which is the proportion of trees having diameters less than X_p , and the Weibull parameters, a, b, c is obtained from (2) as,

$$X_p = a + b(-\ln(1-p))^{(1/c)} \quad (3)$$

With the following fitted prediction equations for a , and the 50th and 95th percentiles, X_{50} and X_{95} respectively, the system of three equations with three unknowns can be solved to obtain estimates of the parameters, a, b , and c .

$$a = -0.982644 + 0.073765Hd - 0.379953Hd/A$$

$$R^2 = 0.4778 \quad S_{y.x} = 0.8524$$

$$X_{50} = 12.44178 - 0.04491A + 0.067869Hd - 42.8976/Hd$$

$$- 1.19984\ln(N)$$

$$R^2 = 0.8918 \quad S_{y.x} = 0.3940$$

$$X_{95} = 16.04111 + 0.00868A + 0.093124Hd - 43.7693/Hd$$

$$- 1.72270\ln(N)$$

$$R^2 = 0.9201 \quad S_{y.x} = 0.4898$$

where A = age (years from planting)

Hd = average height of dominant and codominant pine (ft)

N = number of pine surviving (trees/ac)

Given a , X_{50} and X_{95} , and equation (3), estimates of b and c are calculated by

$$\hat{b} = (\hat{x}_{95} - \hat{a}) / [(2.99573)^{(1/c)}]$$

$$\hat{c} = 1.4637 / \ln [(\hat{x}_{95} - \hat{a}) / (\hat{x}_{50} - \hat{a})]$$

Subroutine YIELD uses these equations to generate the diameter distribution.

Height-Diameter Relationships

A number of different models for predicting average total tree height by diameter class were examined including equation forms presented by Feduccia et al. (1979), Bennett and Clutter (1968), Burkhart and Strub (1974) and Lenhart (1968). These models were fitted to the 56,989 planted loblolly pine in the data and the resulting equations were evaluated on fit, predictive ability and exhibition of logical trends. The following model from Lenhart (1968) fitted to the combined data

$$\log(Hd/H_i) = -0.0400 + (1/D_i - 1/D_{max})(0.4284 - 0.4975\log(T_s) + 0.3638/A + 1.0954\log(Hd)) \quad (4)$$

$$R^2 = 0.65 \quad S_{y.x} = 0.041$$

where

\log = logarithm base 10

Hd = average height of the dominant and codominant pine (ft)

H_i = total height of tree i (ft)

D_i = diameter at breast height of tree i (in)

D_{max} = tree of largest dbh in the stand (in)

T_s = number of pine surviving (trees/ac)

A = age (years from planting)

had similar R^2 , MSE and PRESS statistics and exhibited better behavior at the small diameter classes than other models. Consequently, equation (4) was accepted for predicting heights for given dbh values.

Output

Subroutine OUTPUT prints stand and stock tables. Listed at the top of each table are the input values of site index, stand age and number of trees planted per acre. Immediately opposite are predicted values of average height of dominant and codominant trees, and arithmetic and quadratic mean dbh. Predicted for each diameter class on a per acre basis are number of trees surviving, basal area, total cubic-foot volume outside and inside bark, merchantable cubic-foot volume outside and inside bark and cord volume outside bark to a 4-inch top o.b. Average tree height by diameter class is also predicted. Stand totals appear beneath each column. When particular combinations of input variables produce illogical values of the Weibull parameters, b and c , a

note is printed and execution continues to the next decision period.

Cubic foot volumes are computed using the total and merchantable cubic-foot volume equations presented by Burkhart (1977).

$$TVOB = 0.34864 + 0.00232D^2H$$

$$TVIB = 0.11691 + 0.00185D^2H$$

$$MVOB = TVOB(1 - 0.32354(T^{3.1579}/D^{2.7115}))$$

where
 TVOB = total volume outside bark (cu ft)
 TVIB = total volume inside bark (cu ft)
 MVOB = merchantable volume outside bark (cu ft)
 D = dbh (in)
 H = total tree height (ft)
 T = top diameter outside bark merchantability limit (in).

Cord volumes by diameter class are predicted from conversion factors suggested by Burkhart et al. (1972) for old-field loblolly pine plantations.

Any volume or weight equations based on dbh and total tree height can be substituted for the equations presented here. Table 5 lists a few of the many alternative equations for predicting various types of product volumes or weights.

APPLYING THE MODEL

To use COYIELD, three stand characteristics must be specified; they are stand age (years since planting), site index (base age 25) and the number of trees planted or surviving per acre. The remaining input variables are decisions or judgements made by the user. The following is a step-by-step example of how to apply the model using the FORTRAN batch version. The BASIC version is interactive and prompts the user for the necessary inputs.

Example 1

Suppose a land manager has a tract of land where the timber has been cut and the land site-prepared using some site-preparation technique common to the locality. He would like to use COYIELD to obtain predicted yields for the land at specified ages. He knows the productivity of the land is average and estimates the site index at 60 feet (base age 25). Seven hundred trees per acre will be planted. Wood volume above a 4-inch top diameter outside bark is considered unmerchantable as are trees below 5 inches in dbh. He would like predicted yields at two points in time, ages 10 and 25.

Step 1.

Since stand projection is desired, a "1" is typed in column 1 of the first data card (see Appendix 1a).

Step 2.

The next data card is the stand description card for subprogram INPUT1 (see Appendix 1b). The site index (60 feet) is typed in columns 2-3; the stand age (in this case 0) is entered in column 6; the number of planted loblolly pine per acre (700) is entered in columns 8-10. A "0" is typed in column 12 since the age is 0 and thus the number of trees entered in columns 8-10 is the number planted. (For ages other than 0 either the number of trees planted or the number surviving can be used when making projections.) A "4" is entered in column 14 for the top limit and a "5" is entered in column 16 for the merchantable diameter class limit. The manager decides that combined Coastal Plain and Piedmont coefficients for the site index equation will be satisfactory so a "1" is punched in column 18. Since yield tables are desired for ages 10 and 25, two decision cards will be necessary and thus a "2" is entered in column 20. He wants to

put the title STAND PROJECTION -- EXAMPLE on each yield table so a "1" is typed in column 22. No other stand is to be projected so a "0" is entered in column 24.

Step 3

The title card is entered next with the heading STAND PROJECTION -- EXAMPLE typed in any column.

Step 4

The last step is to punch the two decision cards to obtain output at ages 10 and 25 (Appendix 1c). For the first decision card, a "10" is typed in columns 2-3; for the second decision card, a "25" is typed in columns 2-3.

The input and output for this stand projection example is given in Appendix 2a.

Example 2

Stand and stock tables for various combinations of age, site index and number of trees planted per acre can be generated using the FORTRAN version of program COYIELD. For example, suppose a manager desires a range of stand and stock tables for site index classes 50, 60, and 70 feet. The number of trees planted per acre on each site is 600, 700, 800, and 900. Ages at which output is desired are 10, 15, 20, 25, and 30.

Step 1.

Since stand and stock tables are desired, a "2" is typed in column 1 of the first data card (see Appendix 1a).

Step 2.

The next data card to be entered is the stand description card for subprogram INPUT2 (see Appendix 1d). The first site index value, 50, is typed in columns 3-4. The last site index value, 70, is typed in columns 7-8. The increment value for site index, which in this case is 10, is typed in columns 11-12. The first age, 10, is typed in columns 15-16. The last age, 30, is typed in columns 19-20. The increment value for age, which is 5,

is typed in column 24. The first number of trees planted per acre is entered in columns 26-28. The last number of trees planted per acre is entered in columns 30-32. The increment value for number of trees planted, which is 100, is entered in columns 34-36. The desired top diameter outside bark merchantability limit is four inches so a "4" is typed in column 39. The threshold diameter class below which all trees are unmerchantable is five so a "5" is typed in column 42. The combined Coastal Plain and Piedmont site index curves are desired so a "1" is entered in column 44. Finally, no title will be printed with each output so a "0" is entered in column 46.

Appendix 2b shows example input using subprogram INPUT2 and the resulting stand and stock tables for various combinations of age, site index and number of surviving planted pine.

The source listings for both the FORTRAN and BASIC versions of program COYIELD are shown in Appendixes 3 and 4.

EVALUATION AND DISCUSSION

The observed age, site index (combined Coastal Plain and Piedmont coefficients), and trees per acre for the 186 plots were inputted into program COYIELD and basal area and volumes were calculated. The mean residuals (observed minus predicted) for total cubic-foot volume outside bark, total cubic-foot volume inside bark and basal area were 29.4 cu ft, -28.4 cu ft, and -1.5 sq ft, respectively. No significant trends in the residuals were apparent across the range of ages, sites and number of trees surviving per acre. In addition, residual patterns were not observable across state codes, physiographic province or site preparation method.

The number of trees planted and site index for the 75 plots for which an estimate of trees planted existed were inputted into COYIELD and stand projections were made to the age of plot establishment. The average residuals for total volume outside bark, total volume inside bark, basal area and number of trees surviving were 91.5 cu ft, 28.5 cu ft, 2.3 sq ft, and 30.6 trees, respectively.

Stand projection through time for various values of site index and initial number of trees planted produced logical trends in mean annual increment (MAI) culmination. That is, MAI culminated sooner on higher quality sites with greater stocking. Figure 3 illustrates this relationship for site indexes 50, 60, 70 and 80 with 600 and 900 trees per acre planted.

Data from 79 plots in cutover, site-prepared plantations on Champion International lands throughout the Carolinas, Alabama, Mississippi and East Texas were used to validate the separate components of COYIELD and the model as a whole. First, height-age pairs from dominant and codominant stem analysis trees on the plots were used to validate the site index equation. Using the Amateis and Burkhart (1984) site index model with the combined Coastal Plain-Piedmont coefficients, a site index for each tree was determined based on the total height and total age of the tree. This site index value was used to predict heights at each age. A residual (observed minus predicted) height at each age was determined. Second, Smalian's formula was applied to the dominant, codominant and intermediate trees to calculate observed individual tree volumes. Predicted total tree inside and outside bark volumes were calculated using Burkhart's (1977) volume equation. Residual total volume for each tree was determined. Third, using the age, average height of dominant and codominant trees, number of trees surviving and maximum tree diameter for each plot, plus the individual tree heights and diameters, the height prediction equation was evaluated. Predicted total tree

heights were calculated and compared to the observed height. Fourth, in order to validate the Feduccia *et al.*, (1979) survival equation, the number of trees planted was estimated from the planting spacing given in the validation data. This estimate of the number planted was carried forward along the survival curve to the age of plot establishment. The predicted number of surviving trees per acre was then compared to the observed number of trees at the age of plot establishment.

In addition to the individual component evaluations, the entire model (all components combined) was validated using the estimated number of trees planted from the planting spacing and the site index for each plot and projecting each plot to the age of plot measurement. The predicted total basal area and yields (inside and outside bark) were then compared to the observed values at measurement age. Table 6 shows the mean and standard deviation of the residuals for each component of the model and for the entire model. Plots of the residuals failed to show any significant trends across independent variables for any of the components or the entire model.

Cubic-foot volume yields and basal areas for various combinations of age, site index and number of trees surviving were predicted from COYIELD and compared to corresponding predictions from Feduccia *et al.* (1979) and Clutter *et al.* (1984). Predictions of basal area and merchantable volume were, in general, less for COYIELD than for either of the other two systems. This is due primarily to the type of data upon which the models were based. Feduccia *et al.* (1979) used data collected from sites which had been repeatedly burned and grazed and then planted. Clutter *et al.* (1984) apparently had few nonplanted pines and hardwoods in their data. Many of the plots used to develop COYIELD, however, contained significant numbers of volunteers, which may explain the lower predicted yields from COYIELD. Some of the differences may also be attributed to the fact that different tree volume equations were used in COYIELD than were applied by Feduccia *et al.* (1979) or Clutter *et al.* (1984). Tables 7 and 8 summarize these comparisons for various combinations of age, site index and number of trees surviving.

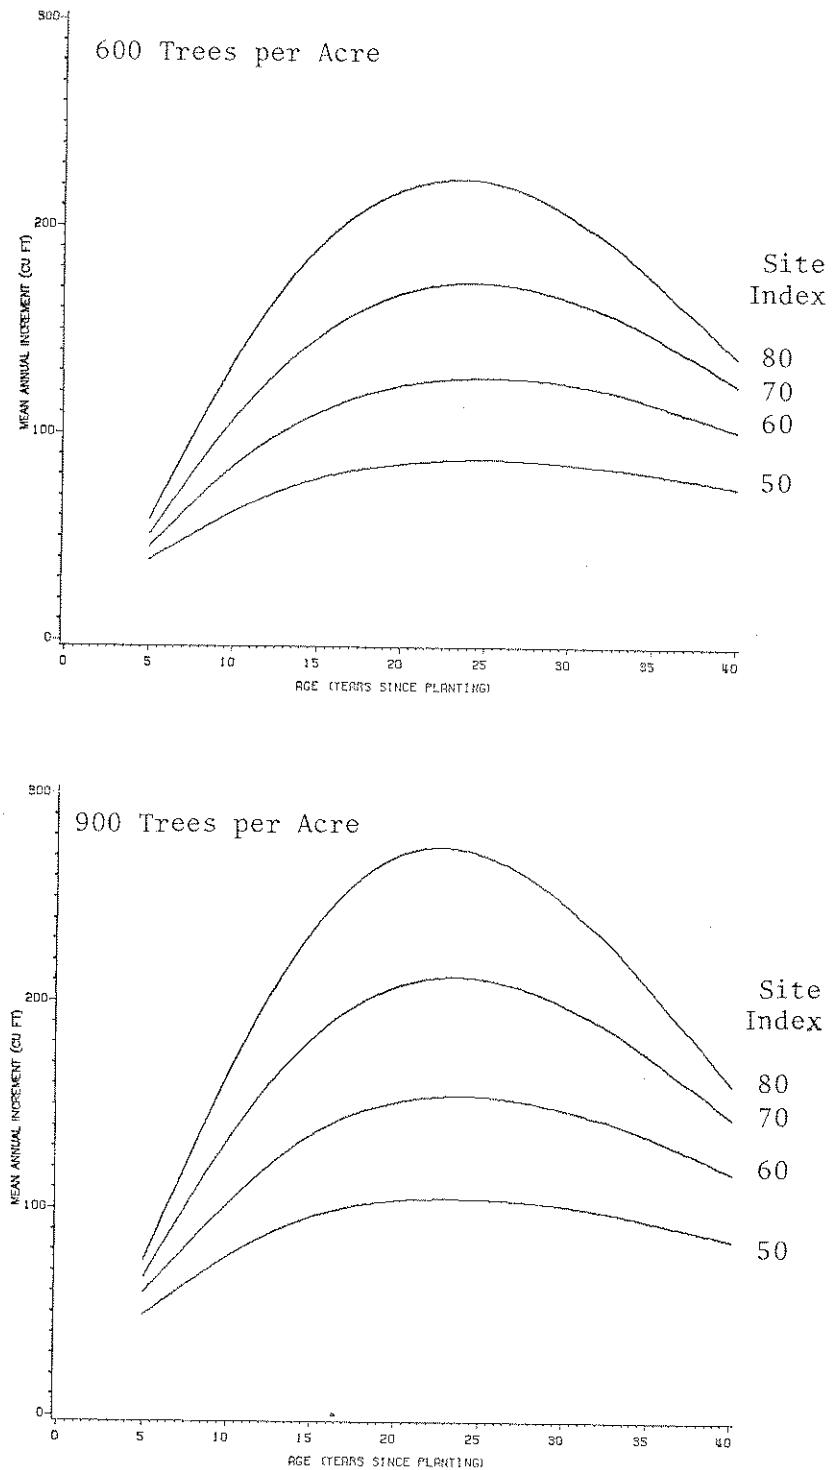

Figure 3. Mean annual increment in total cubic feet per acre for site indexes 50, 60, 70, and 80 with 600 (above) and 900 trees per acre planted.

Table 6. Mean and standard deviation of residuals (observed minus predicted) using data from 79 plots on cutover site-prepared plantations in the Carolinas, Alabama, Mississippi and Texas.

Appendix 2b. Sample stand and stock table output using program COYIELD for various combinations of age, site index and number of trees planted per acre.

Combinations:

Site index : 50, 60, 70 feet (base age 25).

Stand age : 10, 15, 20, 25, 30 years.

Number trees planted: 600, 700, 800, 900

Other Information:

Top diameter merchantability limit: 4 inches o.b.

Threshold diameter class below which
no merchantable timber will be
harvested : 5 inches

Combined Coastal Plain and
Piedmont site index curves.

No title desired

Card Input:

Column: 1 2 3 4 5 6 7 8 9 0 5 0 5 0 5 5

2
5 0 7 0 10 10 30 5 600 900 100 4 5 1 0
